Abstract: A solid-state dye-sensitized solar cell (SDSC) was fabricated with a very thin (~ 650 nm) mesoporous TiO₂ electrode and a donor-antenna (D-A) dye by using 2,2',7,7'-tetrakis-(N,N-di-p-methoxyphenyl-amine) 9,9'-spirobifluorene (Spiro OMeTAD) as hole conductor. A highly transparent thin electrode sensitized with D-A dye showed a short circuit current ($I_{sc}$) of 4.10 mA/cm², an open circuit voltage ($V_{oc}$) of 782 mV and an efficiency of 1.79 % at an illumination intensity of 100 mW/cm² (1 sun, AM 1.5G). TiCl₄ treatment of mesoporous TiO₂ layer resulted in $I_{sc}$ of 6.18 mA/cm², $V_{oc}$ of 737 mV and an efficiency of 2.12% at the same illumination intensity. This investigation demonstrates the possibility of fabrication of SDSC by way of using a very thin and transparent TiO₂ electrode together with a high molar extinction coefficient D-A dye, and the effect of TiO₂ layer thickness on solid-state solar cell performances is discussed.

Keywords: Donor - antenna dye, sensitization, solid-state dye-sensitized solar cell, TiO₂, transparent electrode.

INTRODUCTION

Dye-sensitized solar cells (DSCs) are an attractive alternative for light-to-electricity conversion applications due to their high efficiency and cost effectiveness (O'Regan & Gratzel, 1991; Tennakone, 2001; Thelakkat, 2002). The liquid electrolyte based DSC is composed of a dye-adsorbed mesoporous TiO₂ electrode, electrolyte containing $I^-/I_3^-$ redox couple and a Pt coated counter electrode. Solid-state dye-sensitized solar cells (SDSC) are also promising due to their large potential to convert solar energy to electrical energy at low cost and their capability to solve the leakage or sealing problems that exist in liquid electrolyte dye-sensitized solar cells (Gratzel, 2003). A typical SDSC consists of several different material layers; an optically transparent compact TiO₂ layer; a dye adsorbed mesoporous nanocrystalline-titaniaum dioxide n-type semiconductor layer; solid organic or inorganic p-type layer (hole transport layer: HTL) and a gold counter electrode.

In SDSC, photoexcited dyes inject electrons into the conduction band (CB) of the TiO₂ and electron transport to the anode occurs via diffusion of electrons through the disordered TiO₂ nanoparticles (van de Lagemaat et al, 2006). The diffusion electron transport mechanism plays a decisive role in the mesoporous TiO₂ electrodes because of the absence of an electrical potential gradient in the films (Hagfeldt & Grätzel, 1995; Solbrand et al., 1997). The electron transport is limited by grain boundaries of the TiO₂ network and the residence time of electrons in traps. In SDSC fabricated with a mesoporous oxide layer as electron transport media and 2,2',7,7'-tetrakis -(N, N-di-p-methoxyphenyl-amine) 9,9'-spirobifluorene (spiro-OMeTAD) as hole conductor, one of the major problems is rapid charge recombination due to the weak electron transport property (Hagfeldt & Grätzel, 1995; Solbrand et al., 1997). On one hand, the thickness of the TiO₂ layer has to be the minimum possible for an efficient charge collection by anode. On the other hand, a thicker TiO₂ layer is indispensable to adsorb ample dye so as to absorb greater fraction of incoming sunlight. These two opposing factors, light harvesting and charge collection, lead to an optimal thickness of the TiO₂ layer in SDSCs. A thicker TiO₂ layer results in incomplete pore filling of Spiro-OMeTAD in the mesoporous TiO₂ layer leading to lower efficiency of the cells. i.e. A SDSC fabricated with a semitransparent ~ 2.2 μm thick TiO₂ layer which is sensitized by cis-RuLIV(SCN)₂ (L=4,4V-dicarboxylic acid-2,2V-bipyridine, LV=4,4V-dinonyl-2,2V-bipyridine, Z907)
exhibits an efficiency of ~ 4% at an illumination intensity of 100 mW/cm² with Spiro-OMeTAD as hole conductor (Schmidt-Mende et al., 2005; Schmidt-Mende & Gratzel, 2006). The efficiency decreased to 2% when the TiO₂ film thickness increased to 4 µm. Similar efficiency decreases have been noted for SDSC devices with D-A dye. When ~ 1.3 and 1.7 µm semi-transparent thick TiO₂ layers were sensitized with donor-antenna (D-A) dye such as Ru-TPA-NCS, 3.21 and 1.81% efficiencies have been reported respectively at an illumination intensity of 100 mW/cm² with Spiro-OMeTAD as hole conductor (Peng et al., 2004; Snaith et al., 2008). The observed decrease in efficiency with the increase of TiO₂ layer thickness was due to the combined effects of imperfect pore filling of Spiro-OMeTAD in thick mesoporous TiO₂ and increased charge recombination. Further, the efficient pore filling of Spiro-OMeTAD has been noticed for thinner TiO₂ layers with the compensation of light absorption. These findings revealed the importance of a thinner transparent TiO₂ layer and a dye with a high absorption coefficient in fabrication of efficient SDSC devices. In this report, fabrication of transparent SDSC devices with thin transparent TiO₂ films, D-A dye such as Ru-TPA-NCS dye having high molar extinction coefficient and Spiro-OMeTAD hole conductor is investigated.

METHODS AND MATERIALS

Titanium(IV)bis(acetoacetonato)-di(isopropanoxylate) (TAA) was purchased from Sigma-Aldrich, USA. Glass substrates (Tec 8, 3mm) covered with fluorine-doped tin oxide (FTO) layer having sheet resistances of 8 Ω per square (Ω/□) were purchased from Hartford Glass Co., Inc., Indiana, USA. The TiO₂ blocking layer (bl-TiO₂) was prepared by spray pyrolysis deposition (SPD) technique (Peng et al., 2004). The TiO₂ precursor TAA (titanium acetylacetonate), diluted with ethanol to a concentration of 0.2 M, was used as the spraying solution and pyrolysis was carried out at 400 °C. After the required number of spraying cycles under optimized conditions, the substrates were annealed at 400 °C for another hour before cooling to room temperature. The substrates were kept in an inert atmosphere for further layer preparation. The nanocrystalline TiO₂ (Dyesol - TiO₂ Paste DSL 18NR-T) and terpinol mixture was deposited on the compact TiO₂ layer by screen-printing. The screen-printed TiO₂ was subsequently sintered by stepwise temperature programming (Karthikeyan et al., 2008). The thickness of the TiO₂ layer was varied by using different TiO₂ and terpinol weight ratios.

The TiO₂ layer was coated with dye by leaving them overnight in a 0.5 mM solution of Ru-TPA-NCS dye in Dimethylformamide (DMF). The procedure for the synthesis of the D-A dye has been detailed elsewhere (Karthikeyan et al., 2008). After the physisorbed dye molecules were rinsed away by dipping the samples in DMF, the samples were subsequently dried in vacuum at 45°C for at least 1 h. The hole-transport layer (HTL) was deposited on dye/TiO₂ layer by spin-coating. HTL solution comprises of spiro-OMeTAD (0.16 M), and tert-butylpyridine (0.16 mM) dissolved in water-free chlorobenzene. N-lithiofluoromethane sulfonamide (Li-salt solution, 30 mM) in cyclohexanone was added as the additive. For each substrate, 70 µL of the hole conductor solution was used for spin-coating. To finish, the Au electrode was deposited by electron beam deposition in a vacuum chamber of BA 510 type from Balzers (Liechtenstein) and the active surface was 0.12 cm².

The photovoltaic current–voltage measurements have been carried out by a Keithley 6517 source-measure unit under AM 1.5 G conditions (xenon arc lamp, Air Mass Filters from Oriel). The intensity of light was calibrated with a standard Si-reference cell from the Fraunhofer Institut für Solarenergie (ISE), Freiburg, Germany as 100 mW/cm². All efficiency values reported in this work were not corrected with the spectral mismatch factor. The incident photon-to-photocurrent efficiency (IPCE) values were measured using a lock-in amplifier (SR830, Stanford Research Systems) with a current pre–amplifier. The photovoltaic current–voltage measurements have been carried out by a Keithley source-measure unit under AM 1.5 G conditions. The intensity of light was calibrated with a standard Si-reference cell from the Fraunhofer Institut für Solarenergie (ISE), Freiburg, Germany as 100 mW/cm².

RESULTS AND DISCUSSION

The BET measurement of the surface area of the Dyesol-TiO₂ powder which was sintered at 500 µC was 77.6 m²/g. The BET surface area of the sintered TiO₂ film on FTO glass was not measured, but it was expected to be lower than that of the powdered sample. Figure 1 shows the...
the X-ray diffraction (XRD) patterns of sintered Dyesol-TiO₂ powder and Dyesol-TiO₂ film on FTO conducting glass. It is evident from the figure that the crystals of both TiO₂ powder and TiO₂ film have pure anatase (101) phase. Taking into account the fast electron transport and high surface area, anatase TiO₂ is the preferred phase for efficient functioning of SDSC (Karthikeyan et al, 2007 a, b). To gain better and clear understanding of TiO₂ crystal size, shape and film morphology of the sintered TiO₂ films, which in turn govern the performance in SDSC, Stereo Election Microscope (SEM) examination was carried out for different film thicknesses which were prepared by changing the TiO₂ paste/Terpinol ratio (0.1: 1, 0.2:1, 0.3:1, 0.4:1, 0.5:1, 0.6:1, 0.7:1, 1:1, 1.5:1 and 2:1 wt/wt). All those TiO₂ films prepared with different dilutions are highly transparent. Figure 2a shows the SEM image of transparent 0.2:1 diluted Dyesol-TiO₂ thin film. For comparison purposes, the SEM image of semi-transparent ECN-TiO₂ thin film is shown in Figure 2b. It is interesting to note that the nanoparticles in both Dyesol-TiO₂ and ECN-TiO₂ films have similar shapes and they are well connected with an optimum pore size. Such a well-connected nanoparticle network is desirable for efficient functioning of SDSC because it will improve the electron percolation of the

system. However, the crystal size of Dyesol-TiO₂ is 5-10 nm, whereas ECN-TiO₂ has a large size distribution (10-80 nm). The thickness of the Dyesol-TiO₂ film as a function of dilution of the TiO₂ paste was analyzed by cross-section SEM images of the films. Figures 3a and 3b show the cross-section SEM images of 0.2:1, 0.6:1 and 1.4:1 (wt/wt) diluted Dyesol-TiO₂ films, and the calculated film thicknesses as a function of dilution is given in Table 1. As shown in Table 1, the thickness of the TiO₂ film varied from ~300 nm to ~3.5 µm for 0.1:1 to 1.4:1 (wt/wt) diluted TiO₂ pastes respectively. When the cross-sectional SEM images of the Dyesol-TiO₂ film (Figure 4) were examined at a higher magnification, well dispersed uniform sized nanoparticles that were well connected without forming agglomerates were visible. These well connected nanoparticles facilitate efficient charge transport and collection at the device electrodes.

The molecular structure of the Ru-TPA-NCS D-A dye used in this study is shown in Figure 5a. The extended π-electron delocalization in the bpy ligand enables the D-A dye molecules to have very high molar extinction coefficients ~ 58,000 λmol⁻¹ cm⁻¹ at 440 nm and 25,000 λmol⁻¹ cm⁻¹ at 540 nm (Karthikeyan et al., 2008). The extended separation of electron and holes realized in Ru-TPA-NCS has been shown to retard the recombination process at the TiO₂-dye interface and at the TiO₂-hole conductor interface in solid state solar cells (Handa et al., 2007; Boschloo et al., 2008). This is of particular interest in SDSCs employing organic hole transporting materials (HTMs) as it suffers from fast interfacial charge recombination losses relative to liquid electrolyte based devices. Figure 5b shows the absorption spectra of Ru-TPA-NCS adsorbed Dyesol-TiO₂ films as a function of film thickness. For this study, the thickness of TiO₂ film was changed from 300 nm to 2.4 µm. It is clear that thicker samples show better adsorption of the dye compared to thinner ones. It is also evident from Figure 5b that the dye uptake increases linearly with the increase of the TiO₂ film thickness. The quantification amount of adsorbed dye on Dyesol-TiO₂ film cannot be performed accurately owing to difficulty of complete desorbing of the adsorbed Ru-TPA-NCS dye on Dyesol-TiO₂ films.

Since these donor-antenna dyes have extremely high molar extinction coefficients, it is possible to use thinner TiO₂ layers having comparable optical density to that of a thicker TiO₂ film in SDSC application. In order to check this principle, the influence of TiO₂ thickness on SDSC performance was studied using D-A dye Ru-TPA-NCS. I-V characteristics of solar cells fabricated with different TiO₂ film thicknesses (300 nm - 2.4 µm thick TiO₂ films) sensitized with Ru-TPA-NCS dye are shown in Figure 6a and Table 2. Figure 6b shows the plot of variation of short circuit photocurrent density (Iₘ), Vₘ, open circuit potential (Vₜ), a Vₘ sweeps of 727 mV and a fill-factor (FF) of 0.40 resulting in an overall conversion efficiency of ~ 1.05%. Increase in TiO₂ film thickness to ~ 650 nm resulted in increase in Iₘ (4.2 mAcm⁻²), Vₘ (782 mV) and FF (0.45 %). As given in Table 2, the optimum Iₘ (6.72 mAcm⁻²) and efficiency (1.72 %) were noticed when the TiO₂ film thickness was in between 650 – 850 nm and further increase in TiO₂ film thickness resulted in decrease in Iₘ, Vₘ and FF. To investigate the variation of solar cell performance with the variation of film thickness of TiO₂, the shunt and series resistances of TiO₂ films were studied as a function of TiO₂ film thicknesses. The dark current-voltage (dark IV) results for different

**Figure 3:** Cross-section view of the Dyesol-TiO₂ film prepared with different dilutions (a) 0.2:1 (sample B - TiO₂:Terpinol wt/wt), (b) 0.6:1 (sample E - TiO₂:Terpinol wt/wt) and (c) 1.4:1 (sample F - TiO₂:Terpinol wt/wt)

**Figure 4:** Magnified SEM cross-sectional image of the Dyesol-TiO₂ film 0.2:1 (sample B - TiO₂ : Terpinol wt/wt)
TiO₂ film thicknesses are shown in Figure 7. It is evident that all the TiO₂ films show good rectification behaviour. Also, it is clearly evident that all the TiO₂ films have high shunt resistance and the shunt resistance is independent of TiO₂ film thickness due to presence of an effective exciton blocking layer (Nazeeruddin et al., 2008) which in turn blocks the leakage current from the TiO₂ surface to electrolyte. However, as TiO₂ film thickness increases from 300 nm to 2.4 µm, a dramatic increase in series resistance is noticeable. As given in Table 2, the FF decreases as series resistance increases. Increase in series resistance with the increase of TiO₂ film thickness leads to poor charge collection and hence observed decrease in efficiency as a function of TiO₂ film thickness can be justified (Murayama & Mori, 2006).

From these observations we can conclude that increasing the TiO₂ thickness to an optimum value increases the Iᵥsc dramatically leading to higher efficiency compared to thinner cells (300 nm). Higher current for thicker cells is attributed to the higher dye adsorption on thicker TiO₂ films. On the other hand, FF is higher for...
thinner cells due to lower series resistance. From this study it is clear that there should be a good balance between the $I_{sc}$ and FF in order to improve the performance of the SDSC. Furthermore, by cross-section SEM images analysis of hole conductor filled thin and thicker TiO$_2$ films, it was also observed that the pore filling of the hole conductor in thinner TiO$_2$ films is excellent compared to thicker TiO$_2$ films. As a result of poor pore filling in thicker TiO$_2$ films, higher recombination and in turn lower efficiency were expected compared to thinner TiO$_2$ films.

It is well known that the TiCl$_4$ treatment of the mesoporous TiO$_2$ layer increases the overall solar cell performance of dye-sensitized solar cells (Sommeling et al., 2006; O’Regan et al., 2007). To optimize the solar cell performance further, the optimized solar cell was treated with TiCl$_4$ and sintered at 450 °C. As expected, for TiCl$_4$ treated ~650 nm thick TiO$_2$ film, $I_{sc}$ and efficiency increased moderately. The observed $I_{sc}$, $V_{oc}$, FF and efficiency for TiCl$_4$ treated ~650 nm thick TiO$_2$ film are 6.18 mA/cm$^2$, 737 mV, 0.44 and 2.1% respectively. Compared to non-treated films, 25% increase in $I_{sc}$ was observed for the TiCl$_4$ treated films while $V_{oc}$ and FF decreased slightly for TiCl$_4$ treated TiO$_2$ films compared with the optimized SDSC device (650 nm thick TiO$_2$ film). Comparison of dye-uptake (Figure 8) of both TiCl$_4$ treated and non-treated TiO$_2$ films suggest that the
increase in $I_0$ was mainly due to enhanced dye adsorption as a result of increases in the effective surface area available for dye adsorption by increasing the roughness of the TiO$_2$ particles. Further from SEM images shown in Figure 9a and 9b for TiCl$_4$ treated and non-treated TiO$_2$ films respectively, the growth of TiO$_2$ nanocrystallite size after TiCl$_4$ treatment, resulting in enhanced interparticle TiO$_2$ connection, is clearly evident. Hence, enhanced interparticle connections between TiO$_2$ particles may result in enhanced charge collection by the anode through percolation of electrons and thereby increase in both $I_0$ and efficiency (Sommeling et al., 2006; O’Regan et al., 2007).

For the best SDSC device reported to-date, an efficiency of 4% had been reported with Spiro-OMeTAD as hole conductor and the highest efficiency has been achieved with ~ 2 – 2.5 μm thick TiO$_2$ film. Therefore, the 2.1% efficiency reported for a thin transparent TiO$_2$ film (650 nm) in this investigation is remarkable compared to the film thickness of the best SDSC device reported, and could be assigned to high molar extinction coefficient of the D-A dye. The extended π-electron delocalization in the bpy ligand that results enables the D-A dye molecules to have very high molar extinction coefficients—more than twice that of commonly used N-719 dye (Karthikeyan et al., 2007). On the other hand, the D-A dye like Ru-TPA-NCS dye is known to minimize charge recombination processes occurring at TiO$_2$/dye and TiO$_2$/hexachloroethane (HC) interfaces by promoting spatial separation of charges due to the presence of electron donating triphenylamine group in the Ru-TPA-NCS. Therefore, it can be said that a high molar extinction coefficient of the donor antenna dye and extended spatial separation of electrons and holes play a significant role in enhancing the solar cell performance. It is known from previous work that the Ru-TPA-NCS dye provides improved performance in solid state solar cells, due partly to the improved wetting of the dye by the spiro-OMETAD hole transporting layer (Karthikeyan et al., 2007; Handa et al., 2007).

CONCLUSION

An efficient solid-state solar cell was fabricated using 650 nm thick and transparent mesoporous TiO$_2$ electrodes sensitized with donor antenna dye Ru-TPA-NCS and Spiro-OMeTAD as hole conductor. By TiCl$_4$ treatment of the transparent TiO$_2$ electrodes, 2.1 % photoconversion efficiency was achieved. A high molar extinction coefficient of the donor antenna dye and extended spatial separation of electrons and holes in the Ru-TPA-NCS are reported to play a significant role in enhancing the solar cell performance due to the improved wetting of the dye by the spiro-OMeTAD hole transporting layer. Thicker transparent TiO$_2$ electrodes with superior adsorption of Ru-TPA-NCS dye show poor solar cell efficiencies due to poor pore filling of spiro-OMeTAD hole conductor in TiO$_2$ pores. If an efficient pore filling of hole conductor can be achieved in thicker TiO$_2$ films, an even more efficient SDSC device can be fabricated.
